Abstract

The occurrence of supraventricular arrhythmias is associated with an unfavourable prognosis in septic shock. Available trials are difficult to apply in sepsis and septic shock patients due to included cohorts, control groups and because “one size does not fit all”. The priorities in the critically ill are maintenance of the sinus rhythm and diastolic ventricular filling. The rate control modality should be reserved for chronic AF and in situations when the sinus rhythm is difficult to maintain due to extreme stress conditions resulting from a high dosage of vasoactive agents. Electric cardioversion is indicated in unstable patients with an absence of contraindications and is more feasible in combination with an antiarrhythmic agent. Besides amiodarone being preferred for its lower cardiodepressant side effect compared to other agents, drugs with a different degree of betablocking activity are very useful in supraventricular arrhythmias and septic shock, providing echocardiography is routinely used to support their indications within the current summary of product characteristics. A typical patient benefiting from propafenone is without significant structural heart disease, i.e. typically with normal to moderately reduced left ventricular systolic function. Future research should be channelled towards echocardiography-guided prospective controlled trials on antiarrhythmic therapy which may clarify the issue of rhythm versus rate control, the effects of various antiarrhythmic drugs, and a place for electric cardioversion in critically ill patients in septic shock.

Key words: septic shock, supraventricular arrhythmia, atrial fibrillation, propafenone, amiodarone, metoprolol, esmolol, betablockers, electric cardioversion

SEPSIS AND SEPTIC SHOCK ASSOCIATED ARRHYTHMIAS

Septic shock is characterized by a reduced afterload, unstable filling conditions, LV diastolic and systolic dysfunction, catecholamine surge and chronotropic dysregulation, all of which together may lead to rhythm disorders [1–7]. The impact of sepsis-related fever on the heart rate (HR) is also a contributing factor.

An important manifestation of sepsis is autonomic dysfunction with a low HR variability [8] and an inadequately high HR [9]. An inadequately high HR has been shown to downregulate catecholamine receptors [10] and thus may attenuate one’s response to catecholamine treatment. Moreover, an inadequately high HR may further potentiate myocardial impairment, lead to arrhythmias and worsen diastolic function and filling [11, 12] with a subsequent

decrease in stroke volume. More than 50% of patients with heart failure in the ICU display diastolic heart failure, often associating with a rhythm disorder [13].

Amongst the general ICU population, the incidence of SV arrhythmias is increased in septic shock patients, and is associated with worse short and long-term prognoses [14–16].

The most common arrhythmia is a new-onset atrial fibrillation (NOAF) [17], which represents up to 70% of all SV arrhythmias in septic shock [18]. Besides NOAF, 14.5% of patients present with chronic AF [18]. NOAF is associated with a prolonged ICU length of stay and a higher SOFA score, while failure to restore a sinus rhythm is associated with increased mortality [18–20]. A typical time to arrhythmia onset is within the first 72h from the onset of septic shock [5, 18, 19, 21]. The overall cardioversion rate has been reported as

Figure 1. Multivariate analysis showing insignificant 12-month benefit in cardioverting septic shock patients to sinus rhythm (HR 0.67, $P = 0.113$). Data from [18]

between 70% and 87%, including all those with additional electric cardioversion [18, 19, 21].

The reported ICU mortality of patients in septic shock responding to antiarrhythmic therapy was 33.5%, while the 28-day mortality was 43.6%. These were not significantly different to chronic AF patients with an ICU mortality of 38.2% and a 28-day mortality of 41.1% [18]. Despite treatment, according to available data, some 30–35% of patients [5, 14, 18, 19] remain in NOAF. Their ICU and 28-day mortalities were between 45% and 56%, respectively which in the available studies did not reach statistical significance when compared to cardioverted patients [18, 19]. In a recent study [18], the univariate analysis (excluding chronic AF patients) showed a one-year mortality benefit in favour of restoration of SR in septic shock (HR 0.48, $P = 0.002$). However, when adjusting for age, dosage of noradrenaline, SOFA score and presence of CRRT, the statistical significance was not confirmed (HR 0.67, $P = 0.113$, Fig. 1).

ARRHYTHMIAS IN SEPTIC STATES — CAUSATIVE FACTORS

Causative factors for arrhythmias in a septic patient may also be revealed in the medical history, particularly in previous heart disease and medication. Beta-blockers may affect the incidence of rhythm disturbances by betablocker withdrawal [22]. In a recent paper on SV arrhythmias in septic shock patients with high illness severity, antiarrhythmic drugs were taken prior to the admission to the ICU in 58% of patients [18]: 18.8% had received betablockers, 8.1% amiodarone, 1.3% amiodarone and betablockers, 4.7% propafenone and 2.6% digoxine.

Similarly, genetic predispositions or subclinical ischemic heart disease may manifest themselves under circumstances of elevated stress and metabolic demand.

The appearance of arrhythmias may also relate to pathogenic factors. Exotoxins like streptolysin O [23] or pneumolysin with cardiotoxic potential cause septic cardiomyopathy leading to arrhythmias [24]. In pneumococcal infections, platelet-activating factor receptor activation by the bacterial cell wall plays the same role [25]. Endotoxins like lipopolysaccharide of Gram-negative bacteria may contribute to the onset of arrhythmia, probably by its Toll-like receptor mediated action [26]. SIRS cause increased metabolic demand and intracellular derangement, including mitochondrial dysfunction. The effects of inflammatory mediators also promote cardiac arrhythmias.

FLUID THERAPY VS. DIASTOLIC DYSFUNCTION

In septic patients, associated diastolic dysfunction is very frequent (up to 61.8% [27]). In contrast with systolic dysfunction, diastolic dysfunction is an independent mortality predictor [28]. There is an emerging risk of excessive fluid resuscitation and worsening of tissue oedema and hypoperfusion [29] or vice versa, inadequate volume expansion in patients with pre-existing severe diastolic dysfunction [27].

Recent meta-analyses provide a new perspective on Early Goal Directed Therapy (EGDT), which in the setting of contemporary developed intensive care, shows minimal [30] or no [31–33] benefit, yet brings a potential risk of fluid overload during the initial aggressive volume resuscitation, reaching 67% on the first day [34]. Moreover, the widespread application of EGDT after 2001 led to a surge in betastimulation aimed at achieving sufficient central venous blood saturation. The available studies show increased rates of dobutamine and dopexamine administration [35] in septic shock patients with no morbidity and mortality benefit [32]. As a matter of fact, achieving a saturation rate above 65–70% may be associated with an unnecessarily high cardiac output and DO_2 , recalling Shoemaker's concept of supramaximal oxygen delivery. This, together with advocated static measures of preload [36], may expose patients to a potentially arrhythmogenic setting. Static parameters such as CVP (above 8 mm Hg) and PAWP (above 12 mm Hg) may predict adequate preload in some 54% of septic shock patients [37], calling for other functional and dynamic parameters of preload. The administration of betastimulation in poorly controlled preload causes tachycardia, shortens diastolic filling times and leads to falsely elevated static parameters in a hypovolaemic patient. In the context of low afterload, this may also lead to left ventricular outflow tract obstruction which is, in the context of EGDT, reported in high rates (22% [38]). Not surprisingly, ceasing betastimulation as part of EGDT and the administration of low-dose betablockers with the correction of preload has led to a dramatic decrease in mortality [39].

The administration of catecholamine to correct low vascular resistance in septic shock is proarrhythmic in relation to rather parallel than previous preload correction, as well as to the targeted perfusion pressure [40]. Although, it is recommended to initiate vasopressors in septic shock with profound hypotension early [41], this should not be done without adequate parallel preload assessment [42]. The timely administration of vasopressin to reduce a high dosage of vasopressors may taper the predisposition to arrhythmias in septic shock [43].

Therefore, meticulous and repeated echocardiographic assessment of both the cardiac function and the intravascular volume status seems to be the logical approach, keeping in mind that suboptimal volume replacement leads to higher sympathetic tone and thus greater endogenous adrenergic stimulation, along with an elevated need for exogenous catecholamines.

Both conditions, namely fluid overload and hypovolaemia, are triggering factors for developing arrhythmias. Even though the relation of diastolic dysfunction and atrial fibrillation in the non-critically ill population is well documented [44], studies for critically ill or septic patients are needed.

POTENTIAL IMPACT OF MECHANICAL VENTILATION

The effects of mechanical ventilation should not be omitted either. Aggressive modalities and attempts to recruit consolidated lungs without parallel haemodynamic check ups to exclude right ventricular dysfunction may critically increase right ventricular afterload causing acute cor pulmonale and SV arrhythmias [45–47]. Gradual and slow opening of the consolidated inflammatory lungs, ideally in a prone position and with the aid of bedside chest ultrasound and echocardiography, may prevent SV arrhythmias and the aggravation of haemodynamic instability [48] due to IPPV in a patient with severe respiratory failure.

MEDICATION

Besides exogenous catecholamines, antimicrobial agents may increase the risk of arrhythmia in sepsis. QTc prolongation leads to a risk of ventricular arrhythmias, especially torsades de pointes, after the administration of macrolides, fluoroquinolones, halofantrine (antimalarial), pentamidine, azole antifungals [49, 50], as well as with the combination of ceftriaxone and lansoprazole [51] or with antiretroviral drugs [52]. QTc altered after trimethoprim-sulfamethoxazole may be rare [53]. Two studies on non-septic patients [54, 55] showed no difference in the incidence of arrhythmia between different groups of macrolides, indicating that illness severity is probably the most important factor. A recent meta-analysis found no significant potential for provoking arrhythmias in macrolides [56]. Ivabradine

by its I_f (funny current) channel-blocking action slows the sinoatrial node and decreases the heart rate without unwanted compromise of contractility. It should be noted that ivabradine, as a chronic medication, may potentiate the risk of developing NOAF (15% increase in the relative risk) [57]. Its use in critical care is extremely limited by its oral form and poor evidence, although a case series showed a benefit in catecholamine-induced tachycardia [58] and sepsis in cardiothoracic patients [59].

ELECTROLYTE DISTURBANCES IN SEPSIS

Hypophosphatemia is more frequent in the critically ill than in the general population and, besides other negative consequences, is associated with decreased myocardial contractility and a higher incidence of ventricular arrhythmias [60]. A small case series showed that phosphorus supplementation may be beneficial in preventing new-onset arrhythmias in a septic patient [61].

Up to 61% of critically ill patients present with low magnesium levels at ICU admission. Hypomagnesaemia is common in septic patients and is associated with poor outcomes [62]. Both supra- and ventricular arrhythmias are one of the various manifestations of hypomagnesaemia. While the routine supplementation of magnesium is recommended for the general ICU population [63], specific data for arrhythmias in sepsis are not available.

Similarly, hypocalcaemia may be associated with arrhythmias [64]. Although the prolonged QTc interval and ventricular arrhythmias may be provoked by a chronically decreased level of ionized calcium, no studies for sepsis are available [65].

Dyskalaemias are the most known ion abnormalities with arrhythmogenic potential but are not encountered exclusively in sepsis. Potassium levels are closely related with pH and should not be perceived and corrected separately from disturbances of acid-base status.

Hypokalaemia is not uncommonly caused by medication. Hypocalcaemia and hypomagnesaemia should be corrected if the potassium level does not respond to adequate supplementation [64]. Besides medication-related factors, hyperkalaemia may be caused by renal failure in septic patients with inadequate fluid management. Its treatment depends on the severity of symptoms.

ANTIARRHYTHMIC THERAPY

The priorities in therapy of arrhythmias in sepsis and septic shock are to prevent diastolic heart failure, post-tachycardic systolic heart failure and dilatation. This goes hand in hand with the maintenance of stroke volume, cardiac output and myocardial DO_2/VO_2 . Persistent arrhythmia may potentiate microthrombi formation within the heart, in relation to systolic function, the size of atria, ventricles

and valvular disease. This issue has not been fully clarified in the critically ill yet. Minute silent brain infarctions related to cognitive dysfunction have been reported on NMR, even in fully anticoagulated patients with chronic AF while sepsis is often a procoagulant state, with septic encephalopathy of a multifactorial etiology [66, 67].

Besides improving oxygenation, preload and electrolyte corrections, the mainstay of treatment is represented by amiodarone, preferred for its lower cardiodepressant side effects compared to other agents and electric cardioversion [15, 16, 68, 69].

A haemodynamically unstable patient with new onset SV arrhythmia may require immediate electric cardioversion to secure cardiac output and perfusion pressure. The role of electric cardioversion has not been studied in sepsis-related arrhythmias. In cardiosurgical ICU patients, the biphasic modality was immediately successful in restoring a sinus rhythm in 71% of sessions with high rates of early relapse of atrial fibrillation [70]. Its effect may be improved by concomitant antiarrhythmic medication. When electrically cardioverting 24% of septic shock patients on amiodarone and 36% on propafenone, the overall rate of sinus rhythm maintenance was significant (74% and 89%, respectively) [18].

Antiarrhythmic agents are administered in SV arrhythmia, compromising circulation in patients already on an infusion of NAD for septic shock. Ideally, complex haemodynamic monitoring, including echocardiography, is also applied to correct preload and to avoid administering a betablocker or propafenon in severe LV systolic dysfunction.

AMIODARONE

Amiodarone is a class III antiarrhythmic drug, one most widely used in intensive care with the potential to treat both atrial and ventricular arrhythmias. With its long half life, it is eliminated by hepatic metabolism and not by dialysis [71, 72].

In a recent study on septic shock and SV arrhythmias [18], amiodarone was the primary drug of choice in 76% of patients, which was likely due to the haemodynamic instability of patients in septic shock on vasoactive agents. Restoration to SR was achieved in 74% patients while 23.7% of them required additional electric cardioversion. Nevertheless, 26% of patients failing to restore SR were converted to propafenone during the first 24h, which increased overall rhythm control to 86% under propafenone. The median total dose of amiodarone was 3.0 (1.8–4.6) g, given by infusion over 4 (2–6) days with a median of 1.4 (0.9–1.8) g during the first day [18].

Amiodarone carries potentially significant side effects while the evidence of its efficacy in the septic shock population is lacking [14, 15, 73]. This is in contrast to its widespread use.

Amiodarone and its metabolites are not stable in aqueous solutions and therefore must be dissolved in a solvent

which contains a mixture of diluent polysorbate and benzylalcohol which are related to many adverse effects, particularly due to their lipid solubility.

Its adverse effects involve many organ systems and result in cessation of the medication in 10% to 15% of patients. Amiodarone contains iodine and interferes with thyroid function. Thyroid dysfunction has wide range from hypothyroidism [74] to triggering of hyperthyroid crisis with lengthy consequences [75].

Hypotension due to vasodilatation, and particularly QTc prolongation, have been observed. This may trigger the occurrence of torsades-des-pointes type of ventricular tachycardia. The side effect can be potentiated by concomitant drugs like antihistamines, antimalarials, antipsychotics, lithium, tricyclic antidepressants, antimycotics, or some antimicrobials [71, 72].

Other important side effects include corneal microdeposits, hepatic dysfunction (1–2% in intravenous use) [76, 77], pulmonary fibrosis (in 5–10%), slowly progressive interstitial pneumonia with bilateral diffuse infiltrates [78, 79], skin discoloration and neuropathies [71, 72].

PROPAFENONE

The use of 1C class antiarrhythmic drugs in SV arrhythmia treatment has not been properly evaluated in the critically ill. There are only a few case reports describing serious adverse effects apparently related to their dose-related cardiotoxicity [80–82]. Moreover, their usage has been discouraged by reports describing cardiotoxicity and poor outcomes on long-term use in the cardiology population [80]. Consequently, 1C class agents, like propafenon and flecainide [83], are not routinely used in the critically ill, regardless of the limited application of these conclusions for fully monitored intensive care patients. Propafenon is derived from propandiolamine, which is a chemical compound of betablockers, and acts on the rapid depolarizing phase (phase 0) and also, to minimal extent, on beta-adrenergic receptors [73, 84].

A recent study [18] suggests that propafenon could be a drug of choice in septic shock patients with normal to moderately reduced EF-LV. In addition, the benefits of propafenon have been proved in patients where amiodarone is not capable of maintaining the SR. The routine dosage might be capable of restoring SR without an adverse effect on haemodynamics and with a possible benefit on the outcome (Figs 2, 3). Propafenon was used as a primary antiarrhythmic in septic shock in 17.5% of patients. The pool of patients on propafenone rose to 33% after administering the agent in patients who were not able to cardiovert and maintain a sinus rhythm on amiodarone [18]. There was an overall cardioversion success rate of 86.1% at 24h, while 35.5% needed additional electric cardioversion to achieve

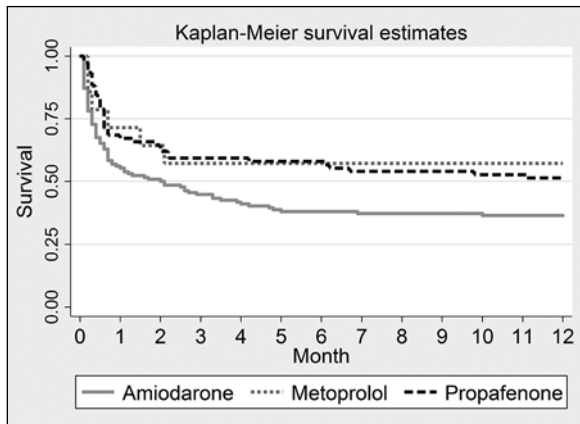

Figure 2. Univariate analysis showing long-term survival of those with propafenone-treated SV arrhythmias similar to those treated with metoprolol and higher than in amiodarone-treated patients (HR 1.76 [1.06; 2.3], $P = 0.024$). Data from [18]

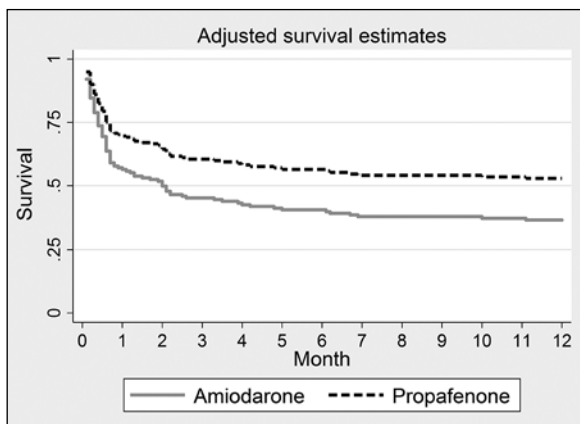

Figure 3. Multivariate analysis showing adjusted 12-month survival benefit in favour of propafenone vs. amiodarone (HR 1.58 (1.04; 2.4), $P = 0.03$). Data from [18]

SR. The chance of cardioverting seems to be significantly higher under propafenone than in amiodarone and is almost the same as under the betablocker, metoprolol (93%).

The median propafenone dosage was 2.5 (1.0–4.0) g while the duration of treatment was 5.0 (2.0–8.5) days. The median propafenone dose was 670 (460–700) mg/day. A 12-lead ECG was routinely taken every 12 hours on propafenone, while no ventricular arrhythmias or conduction disorders requiring treatment other than adjustment of the rate of infusion were observed [18].

Administering propafenone for SV arrhythmia in septic shock is associated with insignificantly lower ICU and 28-day mortalities compared to amiodarone. In contrast, a statistically significant 12-month mortality benefit in favour of propafenone was found (Figs 2, 3). This result might be influenced by a baseline characteristic of the propafenone group not included in the multivariate analysis, one which needs to be clarified by a prospective study.

Although the higher mortality of the amiodarone group (Fig. 3) may be explained by its less efficient antiarrhythmic action, there were other major confounding factors. While being statistically not significant, the LV systolic function was higher in propafenone and betablocker patients compared to those on amiodarone. The dosage of NAD was significantly higher in the amiodarone group compared to the other two, likely reflecting the severity of septic shock. Nevertheless, compared to propafenone, the higher illness severity presumed in the amiodarone group was not found to be associated with any other available strong outcome predictor, such as rates of CRRT, procalcitonin, SOFA and APACHE II scores. Moreover, the dosage of NAD was not related to 12-month mortality in a multivariate regression analysis [18].

Drugs with a different degree of betablocking activity are very useful in SV arrhythmias while septic shock providing echocardiography is routinely used to support their indications within the current summary of product characteristics. A typical patient benefiting from propafenone is without significant structural heart disease, i.e. typically with normal or mildly reduced left ventricular systolic function.

BETA-BLOCKERS

Beta-blockers are a potential option in order to manage sepsis-related atrial fibrillation, both for prevention and treatment. A beta-blockade withdrawal syndrome is a risk factor for atrial fibrillation. Likewise, decisions regarding the administration of a betablocker should consider chronic beta-blockade status [22].

The discussion about the use and effect of betablockers in sepsis has lasted for decades. In contrast, we have faced an era of betastimulation since the 1980s which somehow culminated with the Surviving Sepsis Campaign [36] with a possible impact on myocardial function [29].

Autonomic dysfunction in septic shock may be accompanied by extreme tachycardia and high cardiac output. Protecting the heart under stress conditions requires one to reduce the unnecessary load of catecholamines and the stimulation of their receptors [9, 85]. Studies show that using the easily titratable betablocker esmolol may be safe in those patients who require NAD in parallel for low SVR and hypotension.

The reported benefits of betablockers in sepsis and septic shock [86–90] could be related to the extension of diastolic filling time, improvement of LV diastolic function and arrhythmia management. The rates of septic cardiomyopathy [91] suggest an associated risk for arrhythmias. The administration of betablockers with concomitant vasopressors has been shown to have beneficial effects in animal models of septic shock and in cohorts of septic patients [92–96].

Although limiting systemic adrenergic activation may be beneficial, it may be also detrimental in improperly moni-

tored patients with compromised heart function. Moreover, in HR below 100 per min, the infusion of a betablocker may result in a cardiac output inadequate to systemic oxygen demand in septic shock. The importance of at least including echocardiography combined with continuous monitoring, or with repeated echocardiographic exams, is evident.

The current studies on tachycardic patients with septic shock requiring catecholamine administration suggest the benefit of slowing HR by approximately 20% with intravenous administration of the titratable betablocker esmolol.

Mean esmolol infusion rates varied between 213 ± 64 mg h⁻¹ at the start to 273 ± 90 mg h⁻¹ at 24hrs and slowed the HR significantly down from 142 ± 11 per min to 112 ± 9 per min ($P < 0.001$). MAP or SVR did not significantly change during the study and no significant increase in NAD infusion was required. Esmolol tended to increase stroke volume which resulted in no significant decrease in CO or CI during esmolol administration. A continuous betablockade did not induce significant changes in DO₂, VO₂ or OER [97, 98]. A similar impact on haemodynamics was reported by Morelli who used a very low dosage of 100 mg h⁻¹ as part of the applied EGDT protocol with no echocardiography or verification of the absence of contraindications to a betablocker. Although in this setting, the dosage of NAD was reduced, 49.4% of patients received a rescue levosimendan infusion [39].

A new ultra-short beta-blocker with a half-life of only 4 minutes and a high beta-1 selectivity is landiolol, and which has been used for the treatment and prevention of atrial fibrillation. Landiolol has also been shown to be well tolerated in the critically ill for its limited negative inotropic effect and minimal impact on blood pressure [99–101]. The use of low doses ($5\text{--}10$ mcg kg⁻¹min⁻¹) of landiolol is usually sufficient for the cardioversion of AF compared to controls. In sinus tachycardia, landiolol may prevent the occurrence of arrhythmias in a lower dose ($3\text{--}5$ mcg kg⁻¹min⁻¹) [99].

There was no report of bronchospasm when using titrated betablockers in patients with atrial fibrillation [102].

Metoprol is well tolerated in septic shock patients with an SV arrhythmia. In septic shock-related NOAF medicated with *i.v.* metoprolol, a sinus rhythm was achieved in 92.3% patients with no additional electric cardioversion. The median length of treatment was 5 (2–9) days, while the median intravenous metoprolol dose was 84 (48–120) mg day⁻¹ [18].

Betablockers are the medication of choice for a well-selected cohort of septic shock patients [88, 89]. In a recent paper, only 6% of septic shock patients with SV arrhythmias were medicated with betablockers [18]. An indication to use drugs other than amiodarone (betablockers, propafenone) may be also supported by the rates of thyroid disease [73, 75].

DIGOXIN

Digoxin has a dual mechanism of action, slowing cardiac conduction through the AV node and increasing the force of myocardial contraction (inhibiting the sodium-potassium pump, increasing the calcium availability to the contractile apparatus) [103]. Its indication in critically ill is represented, in particular, by atrial fibrillation with rapid ventricular response-rate control therapy. Although most studies include non-ICU patients, there is paucity of data regarding critically ill patients and patients in sepsis and septic shock. Digoxin may reduce the number of hospital admissions when given in combination with ACE inhibitors and diuretics in patients with an EF-LV lower than 45%. Various other metaanalyses and studies have suggested a relationship between digoxin therapy for atrial fibrillation and increased all-cause and cardiovascular mortality in cardiology outpatients [104, 105] or septic patients with low illness severity [106]. A recent metaanalysis showed zero impact on outcomes [107].

All these studies are hardly applicable to closely monitored critically ill patients due to their design, included cohorts of non-ICU patients and no attempt to select those who may benefit from rate control therapy. Digoxin's efficacy decreases with adrenergic stress, which may be limiting in the critically ill. On the other hand, its positive inotropic effect may be beneficial for the treatment of heart failure with left ventricular systolic dysfunction [21, 108].

Moreover, this drug may be very useful in a chronic atrial fibrillation with rapid ventricular response, even in critically ill septic shock patients. While the optimal dosage is between 0.75–1.5 mg, given in 0.125 mg increments according to the optimal ventricular response, the onset of the full effect is usually delayed and the drug should be given with caution in renal insufficiency and in combination with other antiarrhythmic agents.

DISCUSSION

An important issue is the applied definition of sepsis and septic shock. A diagnosis of septic shock is usually made according to the criteria set for systemic inflammatory syndrome [109] with the administration of NAD due to hypotension non-responsive to the correction of preload. In addition, a positivity of at least one inflammatory marker of the monitored CRP and PCT is expected, together with the administration of antibiotics for an infectious source.

The available literature on SV arrhythmias in septic shock shows critically ill patients in septic shock with a high predicted mortality, an IPPV rate of 99% and high rates of CRRT (27–31%) [18]. As of now, all authors have adhered to the septic shock criteria based on volume non-responsive SIRS with a need for a vasopressor and antibiotic therapy administered for an infectious source [109]. Applying the novel septic shock criteria of 2016 [110] may increase specificity at

the cost of lacking the sensitivity to include even those who could potentially benefit from septic shock therapy [111]. In addition, certain studies show high inflammatory markers (e.g. PCT) suggesting a high rate of bacteraemia among patients categorized according to the older SIRS criteria. The SOFA score and a median arterial lactate level may serve as controls adjusting the studied population in the context of the novel septic shock criteria published in 2016 [110].

The ICU routine is influenced by up-to-date haemodynamic monitoring incorporating echocardiography. The combination of ECG and echocardiography allows to indicate antiarrhythmics with the exclusion of a more cardiodepressant medication (betablocker or propafenone) in severe LV dysfunction and also to correct preload when attempting to cardiovert to SR. A hypercontractile ventricle or dynamic LVOT obstruction may rather, after correction of preload, indicate betablocker therapy. Echocardiography also helps one to decide whether to cardiovert a patient with an unknown history of arrhythmia. A finding of a significantly dilated left atrium or valvular disorder may be associated with chronic AF. In the absence of echocardiography, ECG findings of a structural heart disease, such as low R waves in precordial leads, profound ischaemic changes or atrioventricular blockade, would contraindicate propafenone or a betablocker. A known history of moderate or severe LV dysfunction would also exclude other antiarrhythmics than amiodarone.

The clinical applicability of data in the current literature shows some important limitations. Looking at SV arrhythmias in general, one should realize that most of the included patients had atrial fibrillation. Other SV arrhythmias, such as atrial flutter, may be easier to cardiovert electrically while, for example, re-entrant SV tachycardia might be cardioverted by vagal manoeuvres like carotid sinus massage. If searching according to the antiarrhythmic medications used, we again likely missed some patients with SV arrhythmias, e.g. flutter, who were cardioverted electrically and not given antiarrhythmics at all [18]. The application of an echocardiographic protocol before deciding on treatment is also a limitation. Some of the available studies completely lack any attempt to avoid potentially unsuitable medication in an unstable critically ill patient. For example, a large pool (36%) of patients in sepsis was medicated with calcium channel blockers which can help with the rate control at the cost of reducing ventricular contractility and promotion of vasodilatation, which would be difficult to justify in a patient with left ventricular compromise or profound vasoplegia [106]. Beneficial effects, including the outcome improvement of beta-blockers, have been suggested in septic shock patients [86–89]. Nevertheless, the comparisons to control patients were fraught with high mortality in the control group while the haemodynamic monitoring did not

include echocardiography [87]. Several limitations have to be considered including the absence of echocardiographic cardiac function evaluation and the exclusion of the valve and conduction disorders, prior to beta-blocker administration in septic shock patients [88, 90]. The same limitations regarding the absence of echocardiographic screening of cardiac function and haemodynamics exist in all the case series on various antiarrhythmic agents in sepsis and septic shock patients. Along with poorly defined inclusion and exclusion criteria, this might lead to misleading results [80].

Moreover, some of the echocardiography studies comprise rapid bedside assessment in a form of FATE/RACE protocol [112]. Therefore, we have limited dataset on the exact size/volume of the left atrium, various degrees of diastolic function, valve disorders, right ventricular dysfunction and pulmonary hypertension. The reported rates of various degrees of diastolic dysfunction likely underestimate reality [13].

If losing a sinus rhythm transmits so profoundly to the outcome, why we do not have enough data showing that reverting back to sinus [20] improves mortality and morbidity? The answer lies in the absence of critical care trials and the limited applicability of major cardiology trials [113–115] in the intensive care setting. In the long term, the recurrence and side effects of antiarrhythmics have led to tendency to rather provide rate control than rhythm control therapy. Nevertheless, the overlap between rhythm and rate control may be significant as shown in a recent study on perioperative AF where the two modalities included the same antiarrhythmic agents and showed similar rates of electric cardioversion in 25% of the patients included [116]. The rate control approach and resignation to restore the atrial contribution to the ventricular filling contrast with data showing that the loss of atrial kick is associated with two to five times increased mortality [5, 14, 21]. Various degrees of deterioration of the diastolic function in septic shock patients are associated with the prognosis. A left ventricular relaxation disorder is more dependent on atrial filling, as well as a pseudonormal LV filling compared to a restrictive LV filling with a possibly dilated poorly contracting left atrium. In parallel, this classic stratification of diastolic dysfunction relates to patient's prognosis in septic shock (2). Again, the available trials (PRCT) included all degrees of diastolic dysfunction without any attempt to stratify the degree of dependence of the ventricular filling on the atrial systole. Moreover, with exemption of the AF-CHF trial [113], the authors included all patients without stratification of the LV systolic function, and related left atrial remodelling which relates to the ability to maintain a sinus rhythm [117, 118].

The median age in an adult ICU varies around 55–65 years with a significant prevalence of hypertension and ischaemic heart disease. This suggests a large proportion of patients with dependence on ventricular filling of atrial sys-

tole, thus suggesting a potential benefit of rhythm control. The prevalence of NOAF and a broad spectrum of potentially reversible triggers in the critically ill offer a better opportunity for cardioversion and maintenance of a sinus rhythm in closely monitored patients than in cardiology outpatients.

CONCLUSIONS AND FURTHER RESEARCH

In conclusion, current data confirms the mortality impact of an acute onset SV arrhythmia in the critically ill, here in the context of septic shock [14, 15]. Therefore, actively pursuing SR and cardioverting patients may contribute to the treatment of diastolic dysfunction with a positive impact on mortality. Available PRCTs are difficult to apply for NOAF in the sepsis and septic shock patients due to included cohorts, control groups and because “one size does not fit all.” The rate control modality should be reserved to a chronic AF and in situations when a sinus rhythm is difficult to maintain due to extreme stress conditions due to a high dosage of vasoactive agents. The electric cardioversion (preferably biphasic) is indicated in unstable patients with an absence of contraindications and is more feasible in combination with an antiarrhythmic agent. Future research should be channelled towards echocardiography guided prospective controlled trials on antiarrhythmic therapy which may clarify the issue of rhythm versus rate control, the effects of various antiarrhythmic drugs and a place for electric cardioversion in critically ill patients in septic shock.

ACKNOWLEDGEMENTS

1. This research has been supported in part from project reg.no. CZ.2.16/3.1.00/21565 from OP Prague Competitiveness. The sponsor did not have any role in the interpretation of the data, in the writing of the paper and in the decision to submit the article for publication.
2. Conflict of interest: none.
